

100 YEARS AGO

When the year's work is over and all sense of responsibility has left us, who has not occasionally set his fancy free to dream about the unknown, perhaps the unknowable? And what should more frequently cross our dreams than what is so persistently before us in our serious moments of consciousness – the universal law of gravitation. We can leave our spectroscopes and magnets at home, but we cannot fly from the mysterious force which causes the rain-drops to fall from the clouds, and our children to tumble down the staircase. What is gravity? ... Lord Kelvin is quoted as having pointed out that two sources or two sinks of incompressible liquid will attract each other with the orthodox distance law. Let us dream, then, of a world in which atoms are sources through which an invisible fluid is pouring into three-dimensioned space. ... sinks would form another set of atoms, possibly equal to our own in all respects but one; they would mutually gravitate towards each other, but be repelled from the matter which we deal with on this earth. ... When the atom and the anti-atom unite, is it gravity only that is neutralised, or inertia also? May there not be, in fact, potential matter as well as potential energy? And if that is the case, can we imagine a vast expanse, without motion or mass, filled with this primordial mixture, which we cannot call a substance because it possesses none of the attributes which characterise matter, ready to be called into life by the creative spark? Was this the beginning of the world?

From *Nature* 18 August 1898.

50 YEARS AGO

The trouble in Palestine sets back the clock on the recent efforts of both Arab and Jewish gardeners to develop the horticultural attractions of the Holy Land, for the palm boulevards of Jaffa, and the flower-growing settlements at Mishmar-Hasharon, etc., had attracted much praise and attention. The danger, however, goes deeper, for modern Palestine was not the primitive wilderness of brigand and bedouin as depicted in most of the Western religious books. Several excellent gardens and plant collections were in the country, and their future is threatened by the bitterness of war.

From *Nature* 21 August 1948.

increase physical and chemical weathering, pulling more CO₂ out of the atmosphere and so cooling the global climate⁸.

The near-consensus of papers in a volume devoted to this topic⁹ makes the uplift-weathering hypothesis a leading explanation for global cooling during the past 20 Myr. Still, ignorance of uplift histories across much of Tibet has made the hypothesis difficult to evaluate in full. In particular, with little direct evidence for uplift before 20 Myr ago, it is hard to claim that Tibetan uplift caused, or was even involved in, the global cooling that began 55 Myr ago and led to Antarctic glaciation by 36 Myr ago¹⁰.

If large-scale uplift did occur in north-eastern Tibet as early as 37–33 Myr ago, chemical weathering of this high terrain could have contributed to global cooling then. Other evidence supports this idea. A striking increase in the global-ocean ⁸⁷Sr/⁸⁶Sr ratio began 40 to 35 Myr ago, and the extra ⁸⁷Sr probably came from the Tibet–Himalaya complex¹¹, from both accelerated weathering and the exposure of rocks rich in ⁸⁷Sr. The early uplift inferred for northeast Tibet

matches the initial upturn in this signal.

Now the question is whether further exploration of Tibet will find evidence of even earlier uplift, especially during the cooling between 55 and 40 Myr ago¹⁰. □

Neurobiology

Making smooth moves

Terrence J. Sejnowski

Whether reaching, throwing, running or dancing, our natural tendency is to make smooth and precise movements. Out of the infinite number of ways that we could have made a particular movement, we generally pick the one that is the smoothest. The current thinking in the field of motor control is that the smooth, stereotyped trajectories made by our motor system are specially chosen to minimize jerkiness^{1,2} and to maximize efficiency³. Or could it be that smoothness is a by-product of a

more fundamental computational goal of the motor system, a goal that only makes us look graceful by accomplishing something else?

On page 780 of this issue⁴, Harris and Wolpert propose an alternative to the principle of maximum efficiency: the principle of maximum precision. On the face of it, making a precise movement does not seem to imply smoothness. Imagine that the goal is to touch an object as precisely as possible in a fixed amount of time. Getting to the spot as

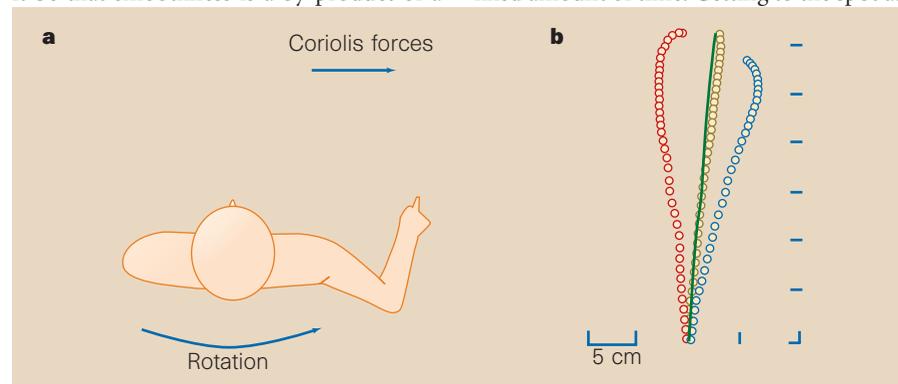

Figure 1 Hand trajectories for reaching before and after rotation of the body, showing that smooth movements are made even after adaptation in an altered environment. a, The subject was on a turntable and slowly rotated. b, View from above of average reaching movements, made in darkness to the position of a visual target that was extinguished just before the subject reached for it. The initial trajectories after the start of rotation (blue circles) were seriously affected by Coriolis forces, but after 40 arm movements (yellow circles) the accuracy and velocity profile of the trajectory was almost identical to that of the original movement (green line). After the rotation stopped, the initial trajectory (red circles) shows the after-effects of rotation. (Adapted from ref. 7.)

quickly as possible and making a careful landing might be a better way to ensure precision rather than making the arm movement as smoothly as possible. What this high-acceleration strategy does not take into account, however, is that the motor neurons that control the arm are noisy and cannot be counted on to get the arm to the same place for the same command. In particular, giving your muscles strong commands is exactly the wrong thing to do because the variability in the muscle output increases with the strength of the command. When they take activity-dependent motor neuron noise into account, Harris and Wolpert find that optimizing the precision of the endpoint of a movement produces smooth movements with exactly the properties of those that we tend to make.

The velocity profiles of arm movements are highly symmetrical around the midpoint of the movement. Simulations of a simple arm controlled by signals that have the same noise characteristics as our motor neurons have similar bell-shaped trajectories when the controller is optimized for maximum precision, over a wide range of parameters such as the inertia, viscosity and time constants. Robustness of the shape of the velocity curve to the details of the arm model is particularly important because the universality of this property⁵ originally inspired the minimum-jerk model of motor control. Not only does smoothness apply to arm movements under normal conditions, it also holds after adaptation in altered environments (Fig. 1). The maximum-precision model also accounts for other universal laws of arm movements, such as those that relate the duration of a movement to the maximum precision attained⁶, and how the speed of movement scales with the radius of curvature. It is also impressive that the model can account for a broad range of movements including saccadic eye movements, pointing movements and rhythmic arm movements.

This explanation is satisfying for three reasons. First, reducing uncertainty should clearly be a primary concern of any movement controller, whereas smoothness might reduce wear and tear but is more of a luxury. Second, the motor system is constantly calibrating itself to improve performance⁷ (Fig. 1), and it is much easier to compute the endpoint error than the degree of smoothness. Finally, grace is a reward for virtue, a bonus for being as accurate as you can possibly be. So we may move through the world smoothly neither by chance nor necessity, but rather because of noise in our motor neurons.

Noise is ubiquitous in the nervous system and is often ignored. The response of a neuron to a sensory stimulus or the output of a motor neuron during an action is highly variable from one experimental trial to the next, so responses are typically averaged over

dozens of trials to reduce the variability. However, we can see clearly and move accurately on a single trial, so it is of interest to look more closely at the limits and possible benefits of neural variability. The existence of invertebrate brains that work at a much higher level of precision and repeatability with many fewer neurons, and the exceptional precision in the timing of spikes in the peripheral auditory and electrosensory systems of vertebrates, suggest that noise is not an inevitable consequence of sloppy components.

To a first approximation, the variance in the firing rate of a neuron is proportional to its rate; in the cortex of the brain, the ratio of the variance to the rate is close to 1, making the spike trains of cortical neurons about as variable as radioactive decay. One possible benefit of having this degree of variability is to keep a neuron poised at its most sensitive region, near the threshold and ready to fire a spike whenever a suitable excitatory signal appears⁸. A neuron that fires with a high degree of variability can carry more information than one that fires at a constant rate, like a metronome⁹. But it is not yet clear how brains take advantage of the bandwidth in the spike timing. There may be other reasons

for neural variability that we do not yet fully appreciate. The observation that, because of noisy motor neurons, we may have to move more smoothly in the outside world, could have a counterpart for internal brain functions that also tend to run smoothly^{8,10}. Noise may not be a problem for neurons, but a solution. □

Pollination

Sunbird surprise for syndromes

Jeff Ollerton

Interactions between plants and their pollinators include some of the most striking and sophisticated of ecological affiliations¹. On page 731 of this issue, Anton Pauw² describes the relationship between the South African plant *Microlooma sagittatum*, a member of the milkweed family, and its pollinator, the lesser double-collared sunbird (*Nectarinia chalybea*; Fig. 1). The importance of this work lies not only in the description and experimental demonstration of a surprising interaction — it also highlights the danger of assuming that a pollinator is known from an analysis of a pollination ‘syndrome’.

Pollination syndromes are suites of flower characteristics (morphology, colour, nectar and odour) that supposedly attract particular pollinators to specific flowers, and allow them to forage at the exclusion of ‘illegitimate’ visitors that would take the floral reward without executing pollination^{1,3}. This idea is superficially tidy, and it appeals to the classifying minds of many biologists. Indeed, some authors have used this concept to infer the pollinators of species even without field data and then to draw far-reaching conclusions about the historical ecology and evolution of such relationships⁴.

But there are problems associated with the syndrome approach. First of all, most

flowering plants are pollinated by a wide taxonomic range of pollinators⁵, and cannot be shoehorned into neat syndromes. Second, the jaw-cracking terminology of the syndrome concept is often imprecise and confusing. For instance, the luridly coloured, foul-smelling flowers associated with ‘sapromyophily’ (literally, flowers that mimic decaying organic material and are ‘loved’ by flies) are often beetle pollinated. An example is the now famous *Amorphophallus titanum*⁶, one of which flowered this June at Miami’s Fairchild Tropical Garden. Finally, and surprisingly (given their wide acceptance), the predictive value of pollination syndromes has never really been tested — there has been little attempt to use these descriptions as hypotheses to verify the usefulness of floral characteristics in predicting what might pollinate a particular plant. The syndrome of ‘ornithophily’ (bird pollination), for example, is typified by tubular, red, scentless flowers. Although many ornithophilous flowers fit this description, many do not; hummingbirds, for instance, can visit a range of flowers, regardless of morphology or colour⁷.

Some workers have recently begun to take a healthily sceptical approach to the syndrome concept^{5,8}. However, there are no published examples in which communities

primers with which to assay *RPS4X* methylation in particular species; primer and underlying sequences have been deposited at GenBank: human, accession no. G36429; chimp and gorilla, G36430 and G36431; rabbit, G36432; guinea pig, G36433; mouse, G36434; rat, G36435; lemming, G36436; squirrel, G36437; dog, G36438; anteater, G36439; hedgehog, G36440; whale, G36441; and horse, G36442. For *SMCX*, PCR primers were chosen from CpG-island sequences found to be conserved between human and mouse: CCTCGGGCCACCATG-GAG and CTGATTTTCGCGATGTAGCC amplify a 117-bp product that includes three CCGG sites in humans and two in mice. We selected these conserved *SMCX* primers after sequencing 5' portions of the mouse transcript (GenBank AF0398940; obtained by 5' RACE cloning) and comparing these with previously published 5' human *SMCX* sequences²⁰.

Y-chromosome homologues. We searched for Y-specific homologues of *ZFX/ZFY* and *SMCX/SMCY* in mammalian species by Southern blotting of *EcoRI*-digested male and female genomic DNAs. For *ZFY*, we used two hybridization probes in separate experiments, with entirely concordant results (Figs 2 and 3): (1) a 395-bp genomic *Bss*HIII fragment¹⁰ from the 5' CpG island of human *ZFY*, and (2) pDPI007, a 1.3-kb genomic fragment containing the zinc-finger exon²⁶ of human *ZFY*. Probes were labelled with ³²P by random-primer synthesis and hybridized overnight to Southern blots at 67 °C (65 °C for pDPI007) in 1 mM EDTA, 0.5 M NaPO₄ pH 7.2 and 7% sodium dodecyl sulphate (SDS). Blots were then washed three times for 20 min each at 62 °C in 0.1 × SSC (1 × SSC = 0.15 M NaCl, 15 mM Na citrate pH 7.4), 0.1% SDS and exposed at -80 °C with X-ray film backed with an intensifying screen for one day. The *SMCY* hybridization probe (pCM4) and conditions were described previously²⁰.

We also searched for Y-chromosome homologues of *RPS4X/RPS4Y* and *SMCX/SMCY* in particular species by cDNA selection, or by screening cDNA libraries. In cDNA selection²⁷, human *RPS4Y* coding sequence (as selector) was hybridized at 55 °C to cDNA libraries (Clontech) prepared from adult male rat, rabbit, dog or cattle liver. Selection products were cloned into plasmid vectors and sequenced. cDNA libraries prepared from adult male dog liver (Clontech) and adult male opossum spleen (Stratagene) were screened with the entire human *RPS4Y* coding sequence as probe, at low stringency (overnight hybridization at 58 °C in 1 mM EDTA, 0.5 M NaPO₄ pH 7.2, 7% SDS; subsequent washing three times for 20 min each at 50 °C in 1 × SSC, 0.1% SDS). Once dog and opossum *RPS4X* clones were identified, by sequencing, these were used as probes for high-stringency rescreening of their respective libraries (hybridization at 65 °C and washes at 65 °C in 0.1 × SSC, 0.1% SDS). We anticipated that *RPS4Y* clones, if present, would be detected in the low-stringency screen but not in the high-stringency screen. In this manner, we identified opossum *RPS4Y* (and *RPS4X*) cDNA clones, confirmed by sequencing (GenBank AF051137 and AF051136, respectively) and mapping studies (K.J. and D.C.P., unpublished results; complete description will be published elsewhere), but in dog we detected only *RPS4X* clones. Similarly, we screened a cDNA library (Clontech) prepared from adult male rabbit liver at low stringency using a 370-bp mouse *Smcx* cDNA fragment (prepared from clone pCM4 (ref. 20) by PCR using primers CCTTCCAAGTTCAACAGTTATGG and CATACGTATGACTCAATAAACTGGG), identifying 13 *SMCX* but no *SMCY* clones.

Signal-dependent noise determines motor planning

Christopher M. Harris* & Daniel M. Wolpert†

* Department of Ophthalmology and Visual Sciences Unit, Great Ormond Street Hospital for Children NHS Trust, and Institute of Child Health, University College London, London WC1N 3JH, UK

† Sobell Department of Neurophysiology, Institute of Neurology, Queen Square, University College London, London WC1N 3BG, UK

When we make saccadic eye movements or goal-directed arm movements, there is an infinite number of possible trajectories that the eye or arm could take to reach the target^{1,2}. However, humans show highly stereotyped trajectories in which velocity profiles of both the eye and hand are smooth and symmetric for brief movements^{3,4}. Here we present a unifying theory of eye and arm movements based on the single physiological assumption that the neural control signals are corrupted by noise whose variance increases with the size of the control signal. We propose that in the presence of such signal-dependent noise, the shape of a trajectory is selected to minimize the variance of the final eye or arm position. This minimum-variance theory accurately predicts the trajectories of both saccades and arm movements and the speed–accuracy trade-off described by Fitt's law⁵. These profiles are robust to changes in the dynamics of the eye or arm, as found empirically^{6,7}. Moreover, the relation between path curvature and hand velocity during drawing movements reproduces the empirical 'two-thirds power law'^{8,9}. This theory provides a simple and powerful unifying perspective for both eye and arm movement control.

The trajectories of eye and arm movements (that is, the change in position and velocity over time) are not inevitable consequences of

the mechanical properties of muscles, but reflect an orchestrated pattern of neural activation by motor and pre-motor neurons. For saccadic eye movements, it has been proposed that trajectories are selected to minimize the time to reach the target¹⁰. For a linear system, the minimum-time requirement results in 'bang-bang' control, where the control signal is instantaneously switched between its maximum positive and negative values to accelerate and decelerate the eye. However, it is difficult to generate the observed symmetrical saccadic velocity profiles with bang-bang control signals^{11,12}. For arm movements, it has been suggested that trajectories are selected to optimize a cost that is integrated over the movement, such as jerk (rate of change of acceleration)^{13,14} or torque change¹⁵. However, there has been no principled explanation why the central nervous system should have evolved to optimize such quantities, other than that these models predict smooth trajectories. Indeed, the advantage of smoothness of movement still remains unexplained. Furthermore, how the central nervous system could estimate complex quantities, such as jerk or torque change, and then integrate them over the duration of a trajectory is also unknown.

We propose that minimizing the variance of the eye or arm's

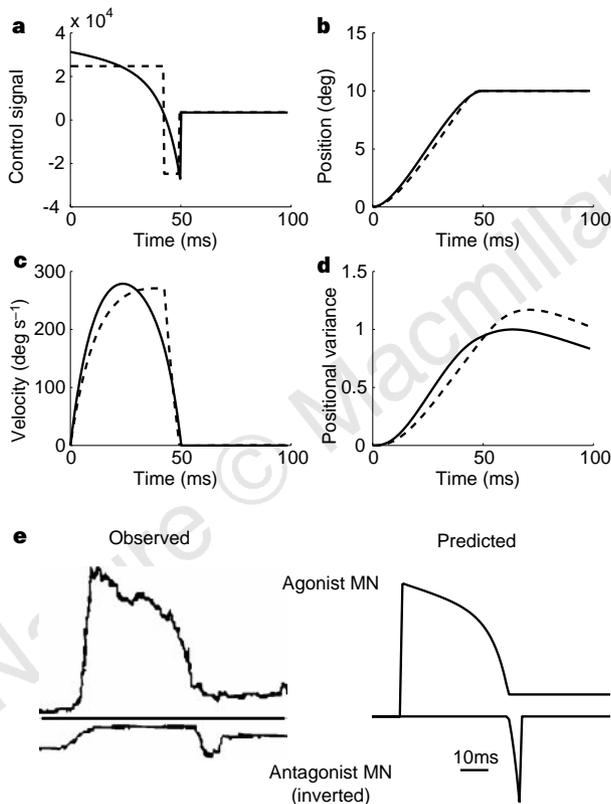

Figure 1 A comparison of bang-bang (dashed line) and minimum-variance (solid line) control for a 10 degree saccade with a duration of 50 ms. **a**, Neural control signals; **b**, average position profiles of trajectories across repeated movements are similar; **c**, velocity profiles show a marked difference in their degree of symmetry; **d**, positional variance (obtained from equation (1) in Methods) which represents the spread of the eye position across repeated trials, about the mean position shown in **b**. Note that the variance continues to evolve after the mean position has become steady. The eye was modelled as a second-order linear system with time constants of 224 and 13 ms. The variances have been scaled so that the peak for the minimum-variance model is unity. **e**, Empirical (from ref. 22, with permission) and predicted motor neuronal firing of agonist and antagonist eye muscles in monkey for a 12 degree saccade. To model the monkey's faster plant, time constants of 150 and 7 ms were used for this simulation. The predicted motoneuronal activity was derived from the control signal by splitting it into positive (agonist) and negative (antagonist) parts (the final tonic level of the antagonist has not been modelled). Note that temporal jitter of firing is likely to broaden and lower the predicted sharp antagonist peak.

position, in the presence of biological noise, is the underlying determinant of trajectory planning. Noise in the final neural control signal (that is, noise in the firing of motor neurons) will cause trajectories to deviate from the desired path. These deviations will be accumulated over the duration of a movement, leading to variability in the final position. If the noise were independent of the control signal¹⁶, then the accumulated error would be minimized by making the movement as rapidly as possible, as in bang-bang control for linear systems. However, here we assume that the noise in the neural control signal increases with the mean level of the signal. This is based on the empirical observation that the standard deviation of motor-neuronal firing increases with the mean level, with a coefficient of variation between 10 and 25% (refs 17, 18). This assumption of signal-dependent noise is also consistent with psychophysical observations that the variability of motor errors increases with the magnitude of the movement, as captured by the empirical Fitt's law⁵. In the presence of such signal-dependent noise, moving as rapidly as possible requires large control signals, which would increase the variability in the final position. As the resulting inaccuracy of the movement may lead to task failure or require further corrective movements, moving very fast becomes counterproductive^{19,20}. Accuracy could be improved by having low control signals, but the movement will be slow. Thus, signal-dependent noise inherently imposes a trade-off between movement

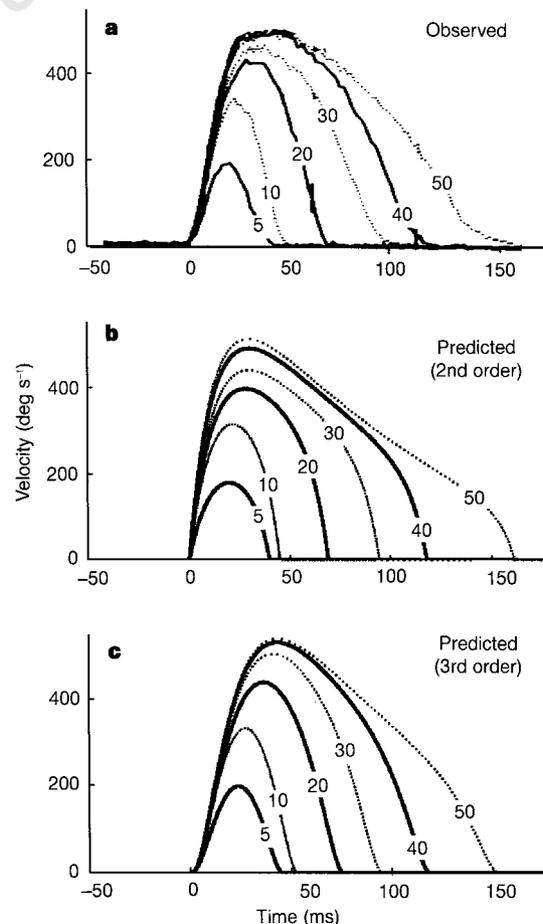

Figure 2 Comparison of empirical and predicted saccade trajectories. **a**, Velocity profiles of actual horizontal saccadic eye movements ranging in amplitude from 5 to 50 degrees (taken from ref. 4, with permission). Saccades below 30 degrees are symmetric, whereas larger saccades are asymmetric with a longer decelerative phase. **b**, Theoretical optimal trajectories for minimizing positional variance with signal-dependent noise for a second-order linear model of the eye with time constants of 224 and 13 ms. **c**, Theoretical optimal trajectories for a third-order linear model of the eye with the additional time constant of 10 ms. The predicted trajectories show the change in symmetry with saccade amplitude.

duration and terminal accuracy. The key point is that for a given amplitude and duration of movement, the final positional variance will depend critically on the actual neural commands and the subsequent velocity profile. We propose that the temporal profile of the neural command is selected so as to minimize the final positional variance for a specified movement duration, or equivalently to minimize the movement duration for a specified final positional variance determined by the task.

We assume that neural commands have signal-dependent noise whose standard deviation increases linearly with the absolute value of the neural control signal. On the basis of this single assumption, we determined the optimal trajectories of the eye and arm that minimized the total positional variance during the immediate post-movement period (see Methods). For saccades, we considered a commonly used second-order linear system²¹, in which the minimum-variance and bang-bang solutions were compared for a 50-ms 10-degree movement (Fig. 1). Both the control strategies reach the target position in the same time (Fig. 1b), but the positional variance in the post-movement period is significantly lower for the minimum-variance solution (Fig. 1d). Although on average the eye is on target, with zero velocity at the end of the movement (Fig. 1b), on any single trajectory there will be a positional error and a non-zero velocity at the end of the movement due to the effect of the signal-dependent noise. Therefore, as seen in Fig. 1d, the positional variance can continue to change after the movement. Thus to minimize deviations from the final position, it is necessary to minimize variance over a post-movement period. The minimum-variance solution results in a smooth symmetric velocity profile, in contrast to the asymmetric profile produced by bang-bang control (Fig. 1c). The model is also in qualitative agreement with observed agonist and antagonist motoneuronal firing patterns²² (Fig. 1e).

Over a range of amplitudes, the minimum-variance solutions (Fig. 2b) also capture the important features of natural saccadic movements (Fig. 2a)—symmetric short movements and asymmetric long movements with an extended deceleration phase⁴. With a third-order model of the eye, the optimal trajectories capture the bell-shaped trajectories observed empirically (Fig. 2c). The optimal trajectories also show a similar rise time for all saccades and a saturation in the peak velocity for saccade amplitudes above ~30 degrees, as is observed experimentally. Although it has been proposed that this saturation arises from limits on the control signal¹⁰, the minimum-variance model predicts this saturation without any such limits. The shapes of trajectories for amplitudes under 20 degrees were insensitive to modest changes in the time constants of the system, whereas these parameters had a much

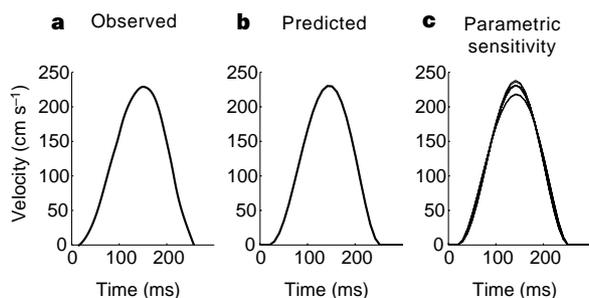

Figure 3 Comparison of empirical and theoretical arm velocity profiles. **a**, Velocity profile of the hand in a typical fast arm movement (taken from ref. 24, with permission). **b**, Theoretical optimal trajectory for minimizing post-movement variance with signal-dependent noise for a second-order skeletal model of a one-dimensional arm with inertia 0.25 kg m^2 and viscosity $0.2 \text{ N ms rad}^{-1}$ driven by a second-order linear muscle with time constants of 30 and 40 ms (parameters taken from ref. 23). **c**, Eight velocity profiles for the model in **b** in which the inertia, viscosity and time constants are individually doubled or halved. The trajectory is essentially invariant to these large changes in the dynamics of the arm.

bigger effect on the slower movements. This is consistent with the general observation that the speed and duration of large saccades have greater variability within and between individuals than those of small saccades. For brief movements, the order of the plant is the major determinant of the optimal trajectory. In the limit, for infinitely brief movements, the highest-order term dominates and the model predicts symmetrical trajectories¹². In Fig. 2, trajectories for second- and third-order models are shown; the trajectories for models of higher order are very similar to the third-order model. For longer movements, the lower-order terms become more important, leading to asymmetrical and complex optimal trajectories.

For arm movements, we first considered a simple one-dimensional fourth-order linear model which captures the muscle dynamics and the arm's skeletal inertia and viscosity²³ (see Methods). The optimal trajectory for a fast movement (Fig. 3b), in which feedback was assumed to play a negligible role, shows the typical bell-shaped velocity profile seen in natural movements²⁴ (Fig. 3a). The profile is again insensitive to changes in the plant, so that even when the inertia and viscosity of the arm or the time constants of the muscle are individually halved or doubled, the optimal profile remains essentially unchanged (Fig. 3c). This is consistent with the observation that when the arm is subject to elastic, viscous or inertial loads, the bell-shaped velocity profile is regained after a period of adaptation^{6,7,25–28}.

For arm movements, the required accuracy varies with the task, as for example in the difference between pointing to someone in a room compared with threading a needle. When pointing at targets, it is empirically observed that movement duration increases with the accuracy demanded by the task. This relationship is captured empirically by Fitt's law, in which the required accuracy is determined by the width of the target (Fig. 4a). For any given movement duration, signal-dependent noise places a lower limit on the final positional variance given by the minimum-variance trajectory. Conversely, given a movement accuracy constraint, specified in terms of final positional variance, there is a minimum duration of movement which can achieve this. We propose that this minimum duration trajectory will be chosen, given the limits of the final endpoint variance imposed by the task. By assuming a linear relationship between the required final endpoint standard deviation

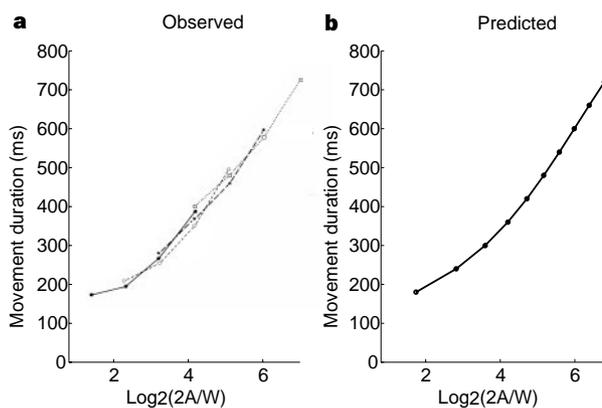

Figure 4 Comparison of empirical and predicted arm movement durations. **a**, Fitt's law relates movement duration (T) to the movement amplitude (A) and target width (W shown as different symbols and lines) according to $T = a + b \log_2(2A/W)$, where a and b are constants. Empirical data from ref. 30 (with permission). This shows the typical increase in movement duration as either the amplitude of movement increases or the target width decreases. **b**, Predicted movement durations for the minimum-variance model in the presence of signal-dependent noise. The movement duration was calculated as the shortest possible, given that the target width places an upper limit on the endpoint positional standard deviation (see Methods). Note the predictions for different widths, W , completely overlap.

and the target width, Fitt's law emerges as a consequence of signal-dependent noise (Fig. 4b).

We next considered a two-joint nonlinear model of the arm moving in the horizontal plane (see Methods). The optimal trajectories for point-to-point movements again showed bell-shaped velocity profiles (Fig. 5d) with gently curved hand paths (Fig. 5b), as observed empirically (Fig. 5a, c)¹⁵. For drawing movements, it has been found that hand velocity (V) decreases as the radius of curvature of the path (R) decreases—this has been formulated as the 'two-thirds power law', $V = KR^{(1-\beta)}$, where K is a constant and $\beta \approx 2/3$ (refs 8, 9). We derived the trajectory that would minimize the positional variance of the hand when repetitively drawing ellipses (see Methods). The optimal trajectory shows the typical slowing down as the curvature increases (Fig. 5e) and reproduces the two-thirds power law, as seen by the regression line in Fig. 5f (slope of 0.32, giving $\beta = 0.68$). This shows that the minimum-variance trajectory predicts the two-thirds power law.

From these analyses, we see that the trajectories of both saccadic eye movements and arm movements can be described as trajectories that minimize post-movement variance in the presence of signal-dependent noise on the control signal. This approach has several important ramifications. Primarily, it provides a biologically plau-

sible theoretical underpinning for both eye and arm movements. In contrast, it is difficult to reconcile observed saccade trajectories with bang-bang control, or to explain the biological relevance of such factors as jerk or torque change in previous models of arm trajectories.

Moreover, there is no need for the central nervous system to construct highly derived signals to estimate the cost to the movement, which is now variance of the final position or the consequences of this inaccuracy, such as the time spent in making corrective movements^{19,20}. Such costs are directly available to the nervous system and the optimal trajectory could be learnt from the experience of repeated movements. Finally, it can be seen that optimal trajectories are inherently smooth. Abrupt changes in the trajectory of the eye or arm require large driving signals which would carry more noise and therefore be suboptimal.

The minimum-variance theory provides a simple, unifying and powerful principle that can be applied to goal-directed movements and implies that signal-dependent noise plays a fundamental role in motor planning. □

Methods

We found the optimal trajectories numerically for both linear models of the eye and arm, and a nonlinear model of a two-joint arm, in the presence of signal-dependent white noise in the control signal. The cost function that was minimized was the positional variance across repeated movements summed over the post-movement period.

Linear models. For the linear models of the eye and arm, we consider a single-input single-output discrete-time system under control with a state-update equation given by $\mathbf{x}_{t+1} = A\mathbf{x}_t + B(u_t + w_t)$, where \mathbf{x}_t is the n -dimensional state at time t , u_t is the neural driving signal at t (note that for arm movements, u_t is the neural command signal that activates muscles and is not torque). A is a fixed $n \times n$ matrix and B is a $n \times 1$ vector describing the dynamics of the system; w_t represents white noise on the driving signal, with zero mean and variance ku_t^2 , which increases with the magnitude of the control signal, u_t , and represents the signal-dependent noise. By iterating the state-update equation, the distribution of the state at time t can be shown to have a mean

$$E[\mathbf{x}_t] = A^t \mathbf{x}_0 + \sum_{i=0}^{t-1} A^{t-1-i} B u_i$$

with covariance

$$\text{Cov}[\mathbf{x}_t] = k \sum_{i=0}^{t-1} (A^{t-1-i} B)(A^{t-1-i} B)^T u_i^2 \tag{1}$$

The variance of the position at time t , V_t , is given by the appropriate element of the diagonal of $\text{Cov}[\mathbf{x}_t]$. We wish to find the driving signal, $\mathbf{u} = [u_0, u_1, u_2, \dots, u_{T+R}]^T$, that reaches the desired position at time step T (the movement time) and maintains it for R steps (the post-movement time) and which minimizes the summed positional variance during this post-movement period, $\sum_{t=T+1}^{T+R} V_t$ (the cost). This can be formulated as a quadratic programming problem which was solved using Matlab.

For the second-order linear model of the eye, the time constants were 224 and 13 ms (ref. 21). Movement durations were taken from ref. 4. Simulations were performed with a time step of 1 ms and a post-movement fixation period of 50 ms. For the third-order model of the eye, an additional time constant of 10 ms was included. There were negligible changes in the optimal trajectories for post-movement times $R > 20$ ms.

For the one-dimensional arm model, we used the combination of a second-order linear model of muscle and a second-order linear model of the arm's skeletal system which included inertia and viscosity. The time constants of the muscle were taken as 40 and 30 ms and the inertia of the arm was 0.25 kg m² and the viscosity was 0.2 N ms rad⁻¹ (ref. 23). Simulations were performed with a time step of 10 ms and a post-movement period of 500 ms. There were negligible changes in the optimal trajectories for post-movement times $R > 200$ ms.

To simulate Fitt's law, we assumed that subjects are required to place any part of their finger of width w (taken as 6 mm) within the target of width W with a fixed probability (the success rate). The required accuracy of the movement,

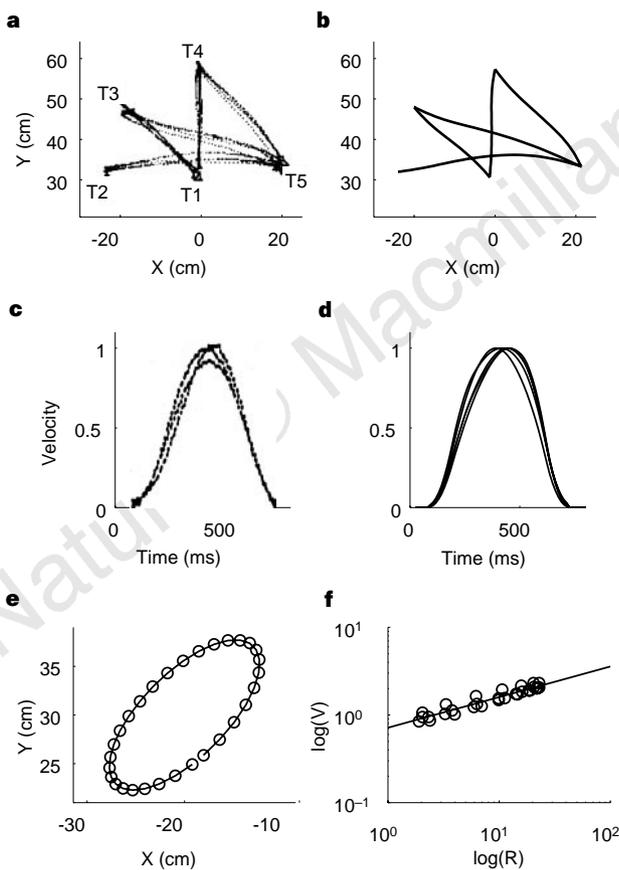

Figure 5 Comparison of empirical and predicted trajectories for a two-joint arm. **a**, Observed hand paths for a set of point-to-point movements (from ref. 15, with permission), and **b**, theoretical optimal hand paths for the same set of movements. The coordinates are centred on the shoulder joint and X and Y directions represent the transverse and sagittal axes respectively. **c**, Observed velocity profiles from T1 to T3 movement in **a**. Note all other movements in **a** showed similar velocity profiles. **d**, Velocity profiles of all the optimal movements shown in **b**, normalized to have a maximum velocity of 1. **e**, Optimal trajectory for drawing an ellipse, the points are equally spaced in time. Note the slowing down at points of high curvature. **f**, Plot of log tangential velocity (V) against log radius of curvature (R). The two-thirds power law predicts $\log(V) = \log(K) + (1 - \beta)\log(R)$. Linear regression gives a slope of 0.32 ($r^2 = 0.85$) and hence the value of $\beta = 0.68$.

specified as the desired final positional standard deviation, was taken as $(W + w)/r$, where r was taken as 1.96 to achieve a 95% success rate. The movement duration was calculated as the shortest possible time that could achieve this accuracy constraint, given that the signal-dependent noise on the entire motor-neuronal pool had a 1% coefficient of variation.

Nonlinear model. For the nonlinear two-jointed planar arm, we used two linear second-order muscles, as described above, acting on the shoulder and elbow joint of a two-link arm moving in the horizontal plane (arm parameters from ref. 29). The trajectories were parametrized as cubic splines with the knots evenly spaced in time. For the point-to-point movements, 7 cartesian (x, y) knots were used with the first and last points fixed at the start and target locations with zero velocity. 500 movements (650-ms duration, sampled at 10 ms) were simulated with signal-dependent noise to determine the trajectory that minimizes the post-movement variance. The optimal trajectory was found using the simplex algorithm to adjust the knot locations.

For ellipse-drawing movements (duration 600 ms, sampled at 20 ms), the knots represented the proportion of the distance travelled around the ellipse as a function of time. Seven knots were used with the first knot at zero and the last at one. This spline determined the velocity profile of the movement which was confined to an elliptic path. The simplex algorithm was used to find the optimal trajectory.

Cortical feedback improves discrimination between figure and background by V1, V2 and V3 neurons

J. M. Hupé, A. C. James*, B. R. Payne*, S. G. Lomber*, P. Girard & J. Bullier

Cerveau et Vision INSERM 371, 18 avenue du Doyen Lépine, 69675 Bron Cédex, France

A single visual stimulus activates neurons in many different cortical areas. A major challenge in cortical physiology is to understand how the neural activity in these numerous active zones leads to a unified percept of the visual scene. The anatomical basis for these interactions is the dense network of connections that link the visual areas. Within this network, feedforward connections transmit signals from lower-order areas such as V1 or V2 to higher-order areas. In addition, there is a dense web of feedback connections which, despite their anatomical prominence^{1–4}, remain functionally mysterious^{5–8}. Here we show, using reversible inactivation of a higher-order area (monkey area V5/MT), that feedback connections serve to amplify and focus activity of neurons in lower-order areas, and that they are important in the differentiation of figure from ground, particularly in the case of stimuli of low visibility. More specifically, we show that feedback connections facilitate responses to objects moving within the classical receptive field; enhance suppression evoked by background stimuli in the surrounding region; and have the strongest effects for stimuli of low salience.

We recorded single units and multiunits (114 single units and 54 multiunits) in areas V1, V2 and V3 of anaesthetized and paralysed macaque monkeys. To study the role of feedback connections from area V5, a small region of the superior temporal sulcus (STS) containing this area was reversibly inactivated by cooling; we then compared the neuronal responses before, during and after STS inactivation. We used visual stimuli consisting of an optimally orientated bar moved across the centre of the receptive field on a background of irregularly distributed, half light and half dark, but lower luminance, square checks (Fig. 1d). In a sequence of interleaved stimulus conditions, the bar and background moved one at a time, or together, in the preferred direction for the cell or its opposite.

Figure 1a–c illustrates a spectrum of effects of the V5 inactivation for single neurons recorded in areas V1, V2 and V3, and stimulated by a bright bar moving in front of a stationary background of lower luminance contrast. A substantial and highly significant decrease in the response to the moving bar is observed in each case during V5 inactivation. Figure 1e, f gives the population data. It is clear that diminution of responses is by far the most frequent effect of V5 inactivation, as observed before for other feedback connections^{6,8}. Of the total sample of sites tested, 33% showed a significant decrease ($P < 0.01$) and 6.5% an increase. Similar effects were observed in infragranular and supragranular layers. No effect was observed in layer 4C of area V1.

The role of feedback connections in figure–ground discrimination was suggested to us when we found that the strength of the effect of V5 inactivation depended on the visibility of the stimuli used for testing neurons in area V3, an area that receives a particularly large feedback input from MT/V5 (ref. 9). We com-
